Chapter 1

General introduction

Biodegradable (bioabsorbable) implants provide temporary support for tissues, where the implants completely dissolve and are absorbed by the body during or after tissue healing, avoiding several drawbacks of permanent implants [1]. The application of biodegradable metallic biomaterials [2–4], including magnesium [5–7], zinc [8, 9], and iron [10], has become more prominent for over a decade in various biomedical engineering and tissue engineering disciplines. Among the mentioned materials, magnesium (Mg) is the most studied metal [11], the reason for which is its suitable mechanical and chemical properties for biomedical applications. Although poor corrosion resistance of Mg is a limiting factor for its application as light structural material, like in the transportation industry, it becomes an interesting characteristic when it comes to the biodegradable materials field for cardiovascular and orthopedic applications [12–14]. The first clinical usage of Mg was reported in 1878, but a renewed interest in it has grown significantly in the last 15-20 years [11]. From the clinical and biomedical perspective, two major concerns about using Mg in clinics are the release of hydrogen gas and surface alkalization due to Mg dissolution [15]. These issues are commonly addressed by alloying, biocompatible coating and surface modification [11]. This chapter includes an overview of biodegradable materials with a focus on Mg, the history of their usage in medical applications, a description of the chemistry of Mg biodegradation, and various computational models aiming to capture this chemistry.

1.1 Biodegradable metals

It has been a very long time since metals have started being employed as implant materials to support, reinforce, repair, or replace damaged tissues

and organs. Historically speaking, iron dental implants were discovered in the remains of a European who perished at the end of the first century AD or the start of the second century [16]. Moreover, gold has been used for the same application in China since ancient times. With more development in materials science and engineering, inert materials such as titanium alloys, cobalt alloys, and stainless steel are widely used nowadays in biomedical implants and devices. However, there are certain drawbacks to these materials in medical applications:

- The release of metallic ions from implants fabricated with these materials can lead to various side effects in the surrounding tissues such as inflammation.
- In some cases, such as for temporary fixation in cardiovascular and orthopedics applications, implant presence is unnecessary after the healing process. Moreover, removing the implant via a secondary surgery may not be a practical solution, causing suffering and pain to the patient again.
- The difference between the elastic modulus of these materials and the surrounding tissues can lead to various mechanical integrity issues. For instance, in the case of bone, this difference causes stress shielding effect, where the implant acts as a shield preventing the bone from receiving enough mechanical load needed for bone remodeling and growth. Additionally, this may cause further mechanical loosening of the implant and secondary bone fracture.

Biodegradable implants would be a great solution to the issues mentioned above. Implants fabricated from biodegradable materials gradually disappear and get absorbed by the body. With more attention to employing these materials in clinical applications, more research studies were conducted to investigate their various aspects. Initially, degradable polymers (such as polylactic acid) were used for this purpose, but later studies showed that they might stimulate the aseptic inflammation of surrounding tissues [1]. Besides, the mechanical properties of polymer materials are not acceptable in load-bearing applications. As a result, biodegradable metals gained more attention in orthopedics where Mg is the most suitable candidate due to its elastic modulus (41-45 GPa) being closest to that of natural bone (2-30 GPa) [17]. In addition to this, especially for bone healing applications, the released metallic ions during the degradation process contribute to the metabolism of the underlying biological process. For example, Mg is one of the most abundant ions found in the bone, and Mg cations have a beneficial impact on

the metabolism of enzymes in the bone regeneration process. Similarly, iron (Fe) plays a key role in oxygen transport in the body, and zinc (Zn) positively influences the physiological functions of bone healing and the formation of different transcriptional factors [18–22].

1.2 Magnesium as a biodegradable material

From the corrosion science perspective, Mg is an active material with a relatively low standard electrode potential of -2.37V , meaning that Mg and its alloys have high corrosion/degradation rate [1]. This property makes Mg and Mg-based alloys a biodegradable metal in biomedical applications, where the materials undergo corrosion in biological and physiological conditions and disappear during or after the damaged tissue is repaired.

From the biological perspective, Mg can contribute positively to the human body's metabolism to improve health. A normal adult body contains 20 – 28g of Mg, from which 27% is distributed in muscles, 65% in bone, and the rest in blood and other tissues [23]. Additionally, Mg contributes to more than 300 enzyme reactions in the body [24]. Extra Mg not needed by the body metabolism is transported via the circulatory system and excreted through the bladder, without causing any major side effect [17].

The first application of Mg for biomedical purposes was recorded in 1878 by Hues, who made artificial radial arteries from Mg and suggested that Mg can be beneficial for the treatment of ovariectomy and hemorrhoids [1]. Payr performed successful animal experiments using Mg tubular vascular connectors in 1900, after which the vessels were reformed, and vascular thickness returned to its normal range after 16 days of implantation [25]. This started a wide range of usage of Mg for cardiovascular applications, a recent example of which is the work by Ikeo et al. for designing V-shaped vascular clips made of Mg-Zn-Ca alloy [26]. In this work, the ductility of Mg was reported to be an added advantage for bearing large plastic deformations that these clips experience. In a relevant study, Erbel et al. implanted 71 stents made of Mg alloys in the coronary arteries of 63 patients. The results showed a similar efficiency and safety for Mg stents to that of other metallic stents [27]. Moreover, Mg stents degraded without any problem after four months. This type of study resulted in acquiring the CE mark for the next generation of Mg stents in Europe [28, 29].

The history of usage of Mg in orthopedics applications started very similarly to its vascular applications. In the study by Payr mentioned above, he also stated that Mg can improve the bone healing rate [25]. Six years later, in 1906, the first Mg-based implant was used by Lambotte for fixation

Figure 1.1: Various potential applications of Mg as a biodegradable metallic biomaterial for cardiovascular and orthopedic implants and devices [4].

of a fracture case [30,31]. This study was followed by many other studies in the last century, the results of which confirmed that Mg could facilitate the bone healing process. However, these studies also demonstrated that the hydrogen gas released during the biodegradation of Mg could lead to inflammation. Furthermore, since Mg's rate of degradation is high, the tissues may not receive enough support before the implants vanish [25]. These issues made the Mg-based implants less common compared to inert metals for orthopedics applications. But, in recent decades, these implants gained more attention thanks to enormous research studies on the biodegradation of Mg to control its side effects and degradation behavior. In 2005, the possibility of using Mg for orthopedics implants was proposed by Witte et al. [32], a suggestion supported by the results of animal studies on femoral implants manufactured from Mg alloys (AZ31, AZ91, WE43, and LAE442). After this study, a wide variety of research works were conducted to investigate the efficiency of Mg-based implants for orthopedics applications [5, 33, 34]. Fig. 1.1 shows the current usage of Mg-based implants and medical devices divided into three categories: commercially approved, on clinical trials, and potential applications [4].

1.3 Chemistry of biodegradation of magnesium

The biodegradation behavior of Mg is investigated in corrosion tests, in which the selection of the corrosive media plays an important role since it affects the underlying chemical reactions [35]. By considering the main application of the biomaterial, which can be tissue engineering scaffolds, vascular stents, or orthopedic fixation devices, the corrosive media can be selected to be a representative of the service environment. The most basic form of the medium is a saline (NaCl) solution, in which the degradation rate is the highest possible [35]. More complex solutions can be used to mimic the behavior of the body environment by taking into account more body fluid components, the most popular of which are Ringer's solution, PBS (phosphate buffered saline), SBFs (simulated body fluids), HBSS (Hank's balanced salt solution), and Earle's balanced salt solution (EBSS) [35]. Adding more organic components to the solution will prepare it to simulate cell culture conditions. The common media for this purpose are MEM (Minimum Essential medium) and DMEM (Dulbecco's modified Eagle's medium) [35]. Fig. 1.2 summarizes various commonly used corrosive media for testing biodegradable metals along with their main components [35].

Various studies have already investigated the effect of different components in the aforementioned corrosive media on the degradation behavior of Mg materials [36–40]. In addition to the presented chemical components, it has been shown that synthetic pH buffers (such as Tris and HEPES) contribute to the biodegradation rate of Mg [36]. The investigations on the effect of different inorganic components, including carbonate, phosphate, sulfate and calcium, show these components' effective contribution to the degradation rate. However, the corrosion protection resulting from the mutual effect of carbonate, phosphate and calcium has been emphasized more [36, 39].

The most common solution for performing corrosion tests on Mg is saline (NaCl) solution, in which the material undergoes aggressive corrosion due to higher electrochemical activities [41, 42]. In a typical aqueous solution, the major corrosion reactions occurring can be written as detailed below [43, 44].

Main, hydrogen evolution reaction (HER):

Secondary, oxygen reduction reaction (ORR):

In this situation, the corrosion products forming on the corroded surface of Mg consist mainly of $\text{Mg}(\text{OH})_2$ and MgO , and the pH in regions close to

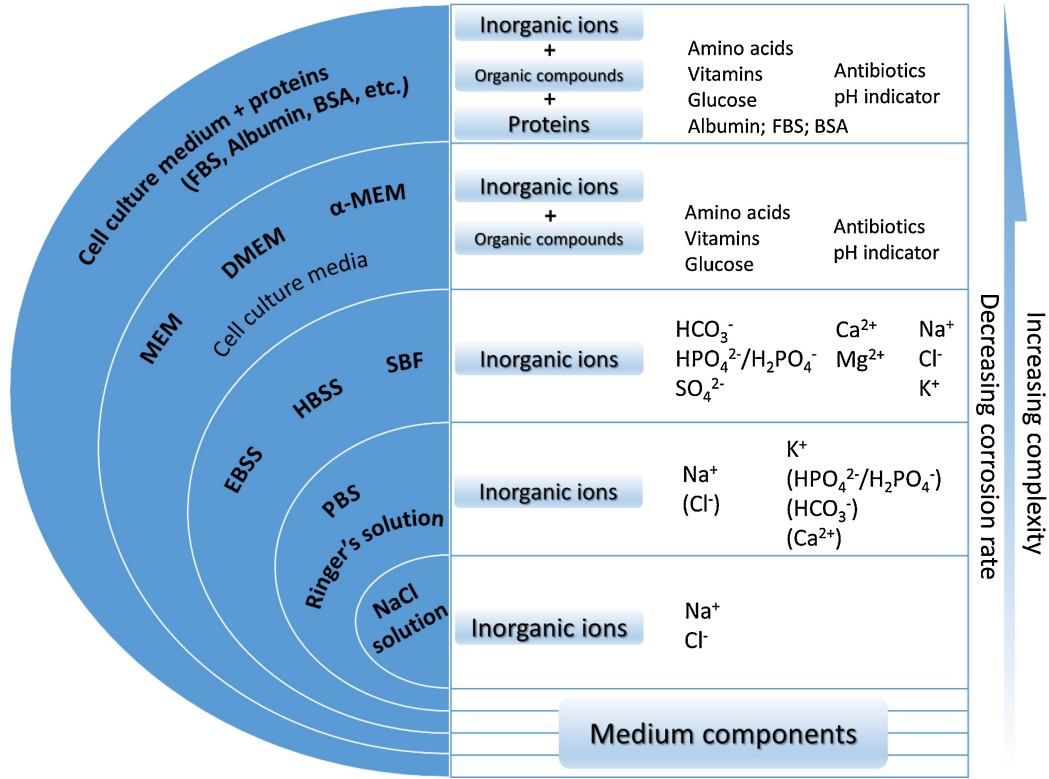

Figure 1.2: A schematic representation of commonly used corrosive media for testing biodegradable metals, sorted by their complexity from the chemical perspective from bottom to top [35].

this surface remains alkaline. In the presence of chloride ions in the saline medium, the formed corrosion product may be broken or bypassed, leading to an increased degradation rate.

The main advantage of using a saline solution for corrosion tests compared to more complex media is that the absence of inorganic ions like carbonate, phosphate, sulfate and calcium allows for investigating the corrosion behavior without concerning possible effect caused by the interaction of these chemical components. On the other hand, the main weakness of saline solution is that it cannot represent the complexity of real body fluid, and as a result, a more complex medium is required to investigate such conditions. To address this issue, more complex saline solutions, such as PBS, are widely used

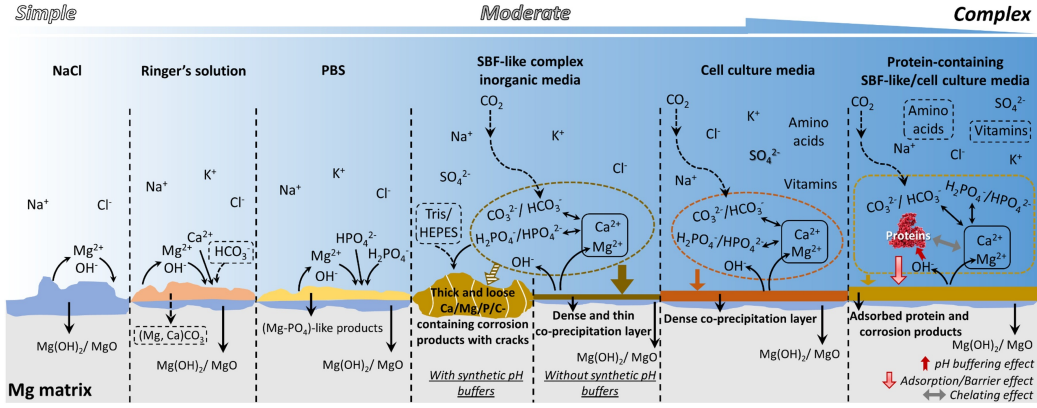

Figure 1.3: A schematic representation of Mg biodegradation behavior in commonly used solutions for corrosion tests of biodegradable metals [35].

for assessing the applicability of Mg alloys in more complex conditions from the chemical perspective [45, 46]. Despite the mentioned limitations, corrosion tests in saline solution are still contributing to understanding intrinsic degradation properties of Mg.

The term "simulated body fluid" is generally used to refer to solutions containing inorganic ions of human serum and interstitial fluid [35]. The commonly used corrosive media in this regard are SBF, HBSS, and EBSS, which all include the same inorganic components yet with a slight difference in their concentrations. A typical composition of these media is chloride, carbonate, phosphates, sulfate and calcium. The individual effect of these components on the rate of degradation of Mg has been extensively studied, where it has been observed that carbonate and phosphate slow down the rate whereas the effect of sulfate is negligible [38, 40]. The concentration of HCO_3^- affects the pH buffering capacity and the degradation rate of Mg simultaneously [47]. The effect of calcium ions is more complex because it does not contribute to Mg corrosion directly. Fig. 1.3 briefly summarizes the various reactions and formed precipitation compositions of the mentioned media for testing the degradation behavior of Mg [35].

There are various evaluation techniques for measuring the degradation rate of Mg, among which the weight loss, hydrogen evolution, potentiodynamic polarization, and electrochemical impedance spectroscopy are the commonly used ones. Generally speaking, the method used for evaluating the degradation rate can affect the reported behavior. For example, it has been shown that in HBSS, the measured corrosion rate of Mg is lower (slower) when evaluated using hydrogen evolution in comparison to the rate found by

direct weight loss measurements [48, 49], which can be due to the secondary dissolution of evolved hydrogen. Moreover, oxygen consumption due to secondary ORR can affect the volume of evolved gas, which is more significant for media with slower degradation rates such as HBSS and MEM [33]. Table 1.1 summarizes the advantages and shortcomings of widely used techniques for measuring degradation rate [35].

Discussing the degradation rate of Mg-based materials can be tricky because as mentioned before, the measurement method and the employed solution can influence the measured degradation rate [50]. However, certain studies have performed this quantitative measurement using different representative media for *in vivo* conditions, resulting in different reported values. The corrosion rate for pure Mg in EBSS was reported to be $0.39 \text{ mm}\cdot\text{year}^{-1}$ [51], but in SBF and HBSS, the reported values are 1.39 [52] and $2.05 \text{ mm}\cdot\text{year}^{-1}$ [53], respectively. Alloying Mg and adding Ca-P coating seems to decrease the degradation rate to $0.25 \text{ mm}\cdot\text{year}^{-1}$ in HBSS [54] and $1.88 \text{ mm}\cdot\text{year}^{-1}$ in SBF [55], although no direct correlation between alloying compounds and the degradation rate has been found yet [56].

Table 1.1: Summary of various common methods to assess the degradation rate of Mg [35]

Test method	Advantages	Shortcomings
Weight loss	High reliability Direct measurement Easily controlled test environment	Non-continuous. Does not reveal varying corrosion rate throughout the immersion Low sensitivity at the initial stages
Hydrogen evolution	Continuous Can be automated Can be performed in closed eudiometers	Performed in open environment in most cases Might show underestimated values of corrosion rate due to secondary ORR and solubility of H_2 in aqueous media
Potentiodynamic polarization	Fast measurement	Non-continuous Open environment measurement in most cases Very often low correlation with long-term weight loss measurements
Electrochemical impedance spectroscopy	Continuous In situ investigation of protective properties of forming corrosion products	Performed in open environments in most cases

1.4 Computational modeling of biodegradation¹

Besides experimental approaches to investigate the properties of biodegradable metallic implants and scaffolds, computational modeling of the biodegradation process and behavior can be used as an efficient tool to design the next generation of medical devices and implants [57]. In addition to traditional modeling approaches for mechanics of materials, it is possible to take advantage of well-developed principles of modeling transport phenomena and numerical simulations to investigate the biodegradation process computationally [58].

Computational models of the biodegradation process vary from a basic implementation of the process to comprehensive mathematical models that capture multiple aspects of the degradation phenomenon. In the category of simplified corrosion models, Gao et al. performed a quantitative study on the change of mechanics during the biodegradation of Mg alloys for cardiovascular applications [59]. Liu et al. developed a fluid dynamics model to characterize the effect of the induced wall shear stress (WSS) on the biodegradation mechanism of Mg stents [60]. They investigated the effect of blood flow velocity and dynamic environment on the degradation of cardiovascular stents. Boland et al. studied the mechanical performance of Mg stents for the treatment of coronary artery diseases using a computational model [61]. Gartzke et al. proposed a degradation model for the corrosion of Mg alloys coupled with mechanical analysis, allowing them to study the change of mechanical properties during the biodegradation process [62]. Another common category of studies in this regard is continuous damage (CD) simulations, in which geometrical discontinuities get translated into the reduction of materials. Despite the limitation of this technique for modeling biodegradation, such as more focus on the mechanical integrity rather than on the fundamental phenomena, it has been used for various relevant studies, such as Gastaldi et al. [63] and Shi et al. [64].

Among the relevant studies, mass transfer-related models were more successful in representing the biodegradation process mathematically. Indeed, the approach of constructing models based on the well-formulated transport phenomena equations and then solving the derived equations using appropri-

¹This section is partially based on a manuscript prepared to be submitted: S. Mukherjee, S. Mandal, M. Barzegari, F. Perez-Boerema, B. Liang, E. Sadeghian Dekhord, L. Groeneveldt, L. Geris, "In silico design and optimization of mesoscopic and macroscopic properties of additively manufactured scaffolds: applications in skeletal tissue engineering."

ate numerical schemes has been followed in recent years to study biodegradation. Ahmed et al. derived a set of mathematical equations to capture the chemical reactions occurring in Mg degradation [65], in which the detailed mathematical equations provided a proper insight into the effect of different chemical components on the biodegradation of Mg *in vitro*. Grogan et al. developed a model to correlate the mass flux of the metallic ions in the biodegradation interface to the velocity of the interface, used to simulate the degradation of complex geometries of Mg-based stents [66]. Similarly, Shen et al. developed a theoretical model to predict the degradation behavior of Mg alloys in orthopedic implants [67]. Their 3D model had a high agreement with *in vitro* corrosion test results.

One of the important applications of biodegradation models is to investigate the change of shape and morphology of the implants and medical devices over time. To this end, appropriate interface capturing methods should be used to track the corrosion interface during the biodegradation process. Bajger et al. developed a mathematical model to study the degradation of Mg implants by reaction-diffusion equations and level-set method (LSM), which enabled them to track the geometrical changes of the implant during degradation [68]. Similarly, Sanz-Herrera et al. developed a comprehensive computational model as a tool for Mg implant design [69]. They combined multiple diffusion-reaction equations to study the change of concentration of the chemical components that play an essential role in *in vitro* biodegradation of Mg implants. A summary of the studies mentioned above is represented in Table 1.2. The reader is encouraged to refer to [70] for a more complete list of recent published mechanistic and phenomenological models of the biodegradation process of Mg-based implants.

The approach taken by Bajger et al. was followed in the current thesis, in which an improved model was developed by considering more chemical components and phenomena, allowing us to perform a more accurate validation using *in vitro* data. Although the biodegradation models are getting more mature and more promising for simulating experimental situations, their integration into other models, such as mechanical stability analysis or neotissue growth, to construct fully-coupled models has remained a challenge. Solving this challenge will enable future models to replicate complex *in vivo* conditions more accurately *in silico*.

Chapter 2

Aims and objectives

This chapter is dedicated to the elaboration of the objectives of the current thesis. It starts with the general definition of the doctoral project aims. Hereafter, the specific objectives of the doctoral project are demonstrated. Then, the chapter illustrates the thesis's outline and structure.

2.1 General aim

The use of biodegradable metals has been gaining attention for various kinds of biomedical applications in recent decades, however, controlling their functionality and behavior inside the body has remained a challenge. Computational modeling of the materials' interaction with the body can help avoid part of the expensive experimental works required to characterize the degradation properties and can provide an integrated spatiotemporal view of the whole process.

One of the most challenging parts of performing such a modeling study is to capture the chemical interactions and the dynamics and kinetics of the reactions occurring on the material-environment interface. Taking advantage of mechanistic modeling principles of mass transfer coupled with free boundary and moving interface formulations seems to be a promising solution to this complex problem. By doing so, one can model the degradation process by a set of equations capturing the interaction of various chemical components while tracking the moving corrosion front, which changes the location where the dynamic is taking place.

In this study, we have developed a mathematical and computational model to predict the biodegradation behavior of biodegradable metallic biomaterials, focusing on Mg. This model enables us to investigate the chemical and, later on, biological phenomena occurring on the corrosion interface of

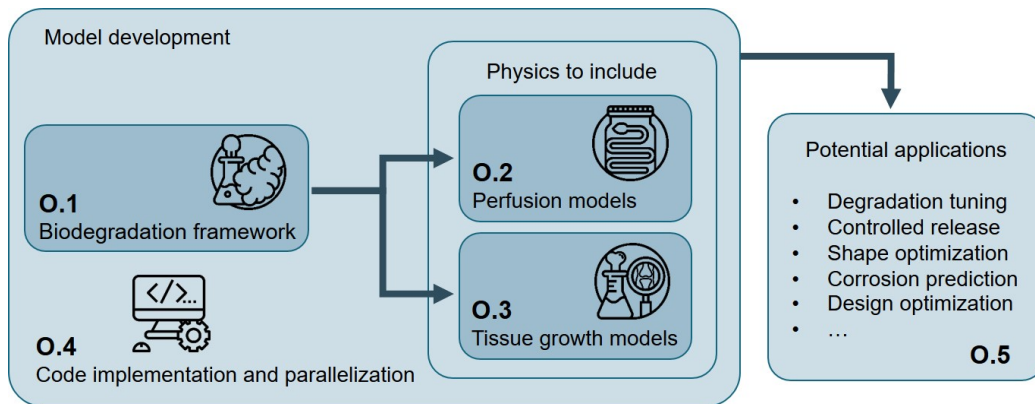

Figure 2.1: Schematic representation of the structure and outline of the current project, divided into five objectives.

these biomaterials. Additionally, coupling the model with other existing cell and tissue growth models leads to a multiphysics model combining the chemistry of biodegradation, the physics of the electrolytes and body fluids flow, and the biology of tissue growth/regeneration. Building such a model requires dealing with several challenges, one of which is to couple various functions used to track the moving boundary of different sub-problems. Moreover, adding the effect of convection imposed by the fluid flow increases the system's complexity. Elaborating these challenges from a mathematical point of view will facilitate future contributions to constructing such models.

2.2 Specific objectives

Despite the advantages of using biodegradable metals in implant design, their fast degradation and uncontrolled release remain a challenge in practical applications. A validated computational model of the degradation process can facilitate the tuning of biodegradation properties. In this doctoral project, a physicochemical model was developed by deriving a mathematical model of the chemistry of biodegradation of Mg and implementing its 3D computational model using the finite element method. To accomplish this, the project was divided into five main objectives, illustrated schematically in Fig. 2.1.

Objective 1 was with the development of the core biodegradation model. For this purpose, a physicochemical model of the biodegradation process of commercially-pure Mg was developed by constructing a mathematical model formulating the mass transfer phenomena and tracking the location of the implant's surface during degradation. For the mass transfer model, a set

of time-dependent reaction-diffusion-convection partial differential equations were derived from the chemistry of biodegradation of the Mg in saline (NaCl) and buffered (SBF) solutions, which usually includes the oxidation of the metallic part, reduction of water and oxygen, changes in local and global pH, and formation of a protective film on the surface of the scaffold which contributes to a slower rate of degradation. Besides these aspects, it was also crucial to consider the effect of different ions in the medium on the degradation rate. Additionally, investigating the structural changes of the scaffolds and implants in practical applications like the resorption of temporary fixation devices, requires tracking the movement of the corrosion surface. This was done by constructing an equation based on the level-set principle, which captured the movement of the medium-metal interface by defining an implicit surface. The derived equations were coupled and solved using the finite element method. The degradation data to validate the models were collected from immersion tests. The model parameters were calibrated using a Bayesian optimization algorithm, and the obtained parameters were used to simulate the pH changes in NaCl and SBF solutions.

Objective 2 was the coupling of corresponding equations of fluid flow (Navier-Stokes and Stokes equations) in the solution domain with the biodegradation model to capture the effect of convection on the degradation process. This was crucial in order to consider the conditions in perfusion bioreactors and hydrodynamics experiments. The main challenge for this step was the complexity of dealing with the finite element formulation of fluid flow equations and the difficulty of defining proper fluid boundary conditions on an implicit interface (the corrosion front).

The **third objective** was to couple the degradation model with the tissue growth models to simulate the response of the surrounding tissue during the biodegradation process. For doing this, a detailed tissue growth model was developed using two different interface tracking techniques, the phase-field and level-set methods, and the results and efficiency of both methods were compared. The mathematical coupling of the degradation and tissue growth models and validating their predictions remained a challenge in this objective.

The **fourth objective** was related to the optimization of the computational aspects of the thesis with all the codes developed in-house using open-source tools and libraries. Detailed work on the parallelization of the computational models of the three previous objectives was carried out to make the developed models run faster. As the required high accuracy on the moving interface increases computation time, parallelization was crucial for the computational models to decrease the execution time of the simulations. The parallel algorithm was implemented using a domain decomposition method. Besides this, the formed linear system of equations in each parti-

tion of the mesh was solved using Krylov methods by taking advantage of available highly efficient preconditioners and iterative solvers, and the scaling behavior with respect to the available computational resources was measured for different components of the models.

The **fifth objective** was the demonstration of the versatility of the developed model by using it as the biodegradation compartment in several multiphysics use-cases to demonstrate the ability of the model to be integrated into other modeling workflows for biomedical applications. In the performed studies, the biodegradation model was combined with structural mechanics and topology optimization codes to deliver a more comprehensive model of the underlying phenomena. The case studies presented in this thesis include mechanical loosening of mandibular bone plates, degradation of an optimized acetabular cup implant, and mechanical integrity of infilled structures.

2.3 Thesis outline

The objectives mentioned in Section 2.2 are tackled in the chapters ahead in the following order and structure:

Chapters 3 and ?? describe the development of the core biodegradation model of **Objective 1**. In **Chapter 3**, a basic biodegradation model is described, which is the base for combining the model with more physics in different applications. **Chapter ??** further develops the base model to include more advanced chemistry from the biodegradation of Mg in more complex electrolytes and conditions.

Chapter ?? describes the development of the fluid flow model used for the simulation of hydrodynamics conditions, which is related to **Objective 2** for coupling the biodegradation model with flow problems. The output coupled model is later used in **Chapter ??** for validating the biodegradation model in hydrodynamics conditions.

The work presented in **Chapter ??** is related to **Objective 3**, in which a tissue growth model is developed to be coupled with the biodegradation model. A simplified tissue growth model is also developed and used in **Chapter ??**, where the rate of bone healing is modeled during the degradation of a mandibular plate, leading to loss of mechanical strength.

Works related to **Objective 4** are presented in **Chapters ??, ??, and ??**, in which the details of software development and model parallelization are elaborated. **Chapter ??** discusses the steps and details of parallelization of the implemented biodegradation model, which can be generalized as a free boundary problem coupled with reaction-diffusion systems. As part of this objective, the developed biodegradation model was transformed into a

multifunctional 3D code called BioDeg, the details of which are described in **Chapter ??**. Additionally, the workflow and routines used to calibrate the models and estimate the unknown parameters are presented in **Chapter ??**, which were also published as educational materials. Furthermore, some parallel scaling behavior results and discussion of the biodegradation model are presented in **Chapter ??**.

In the end, **Chapters ??, ??, and ??** are related to **Objective 5**, dedicated to demonstrating some of the applications of the developed biodegradation model. **Chapter ??** presents the work done to combine the degradation model with the output of a surrogate model, in which the degradation behavior of a patient-specific porous acetabular implant was investigated. **Chapter ??** describes the coupling of the degradation model with a topology optimization code, in which the change of stiffness of some infilled structures was modeled during the degradation process. Lastly, in **Chapter ??**, the biodegradation model was used to predict the rate of mass loss for a mandibular plate, which was subsequently converted to a mechanical strength analysis model to examine how the plate characteristics react to degradation.

To facilitate the structure of the thesis, the chapters related to **Objectives one to three** are grouped in **Part 2** “Model Development”, the chapters related to **Objective 4** are presented in **Part 3** “Code Implementation and Software Development”, and the chapters related to **Objective 5** are presented in **Part 4** “Model Applications”.

Chapter 3

Developing the core computational model

This chapter is based on previously published content in *Corrosion Science*:

M. Barzegari, D. Mei, S. V. Lamaka, and L. Geris, “Computational modeling of degradation process of biodegradable magnesium biomaterials,” *Corrosion Science*, vol. 190, p. 109674, 2021.

Despite the advantages of using biodegradable metals in implant design, their uncontrolled degradation and release remain a challenge in practical applications. A validated computational model of the degradation process can facilitate tuning implant biodegradation properties. In this study, a mathematical model of the chemistry of magnesium biodegradation was developed and implemented in a 3D computational model. The parameters were calibrated by Bayesian optimization using dedicated experimental data. The model was validated by comparing the predicted and experimentally obtained pH change in saline and buffered solutions, showing maximum 5% of difference, demonstrating the model’s validity to be used for practical cases.

3.1 Introduction

3.1.1 Magnesium biodegradation

Due to their bio-friendly properties, biodegradable metallic biomaterials, including magnesium (Mg), iron (Fe), and zinc (Zn), are regaining attention in recent years [2]. These biomaterials find important applications in the design and manufacturing of supportive implants such as temporary devices in or-

thopedics and the cardiovascular field [5,71]. In orthopedics, the biodegradable metallic biomaterials are used as fixation devices, providing adequate support in the early stages while being absorbed gradually during the bone healing process [72]. Implants fabricated using Mg and its alloys are being used for such a purpose [73] due to the similarity of the stiffness between natural bone and Mg, which helps to reduce the stress shielding induced by the implanted device. Additionally, Mg is reported to have a non-toxic contribution to the human body’s metabolism and the bone healing process, which makes the release and absorption of metallic ions safe and biocompatible [74].

Accumulation of mechanistic understanding of Mg degradation achieved by experimental approaches over the years gradually provided a mechanistic understanding of the biodegradation process. Combining these insights with *in silico* modeling approaches enables researchers to study the biodegradation properties and behavior of the implant in a virtual environment prior to conducting any *in vitro* or *in vivo* tests. When fully validated, computational modeling can (in part) replace certain stages of costly and time-consuming experiments verifying the expected degradation behavior of the designed implants. Additionally, the developed models can be efficiently combined with existing computational models to examine other related phenomena such as tissue growth or mechanical integrity.

3.1.2 Computational modeling of Mg degradation

Previous contributions to the computational modeling of the degradation process include a wide range of different approaches, from the basic phenomenological implementations to comprehensive mechanistic models that take into account various aspects of the degradation and resorption process.

Continuous damage (CD) modeling has always been a common approach for corrosion simulation, but from a physicochemical point of view, it focuses on the mechanical integrity of the degradation and neglects the diffusion process. As a result, its application in the degradation modeling of biomaterials, which includes various fundamental phenomena such as mass transfer through diffusion and reaction, is relatively limited. Despite this issue, a CD model proposed by Gastaldi et al. showed a good performance for simulation of bioresorbable Mg-based medical devices [63], in which geometrical discontinuities were interpreted as the reduction of material.

Alternatively, mathematical modeling using transport phenomena equations has shown great flexibility in capturing different mechanisms involved in the biodegradation process. As an example, in Ahmed et al., a set of mathematical equations in cylindrical and spherical coordinates was derived to model the chemical reactions of Mg degradation [65]. Despite the simplic-

ity of their approach from the computational perspective, their model was able to demonstrate the contribution of various chemical components to the *in vitro* degradation of Mg. Similarly, Grogan et al. developed a mathematical model based on the Stefan problem formulation in 1D space to correlate the mass flux of metallic ions into the solution to the velocity of shrinkage of the material during degradation [66]. This was done by considering the mass diffusion and change of the concentration of Mg^{2+} ions, and then, employing an arbitrary Eulerian-Lagrangian (ALE) approach to extend the model to 3D on an adaptive mesh. A similar approach was taken by Shen et al. to develop a theoretical model of the degradation behavior of Mg-based orthopedic implants showing great consistency with *in vitro* test results [67].

An ultimate application of the computational modeling of the biodegradation process of biomaterials can be the prediction of how biodegradation affects the shape of the bulk material, medical device, or implant over time. One of the ways to achieve such a prediction is to capture the movement of the corrosion front mathematically using an appropriate method. The level set method (LSM) is a widely used example in this regard, which is an implicit mathematical way of representing the moving interfaces. This approach was used in Wilder et al. to study galvanic corrosion of metals [75]. They employed LSM on an adaptive mesh to track the moving corrosion interface, but their model lacked a thorough validation using experimental data. Gartzke et al. also worked on a simplified representation of the interface movement by developing a mechanochemical model of the biodegradation process, which helped them to study the effect of degradation on the mechanical properties [62]. They performed a basic qualitative validation on the predictions made by the model. Another similar study in this regard is the Sun et al. work [76], in which a detailed mathematical model was derived and validated to study the deposition of corrosion products on the surface of materials. This mathematical approach was also employed in the biomedical field by Bajger et al. to study the mass loss of Mg biomaterials during biodegradation [68]. They used LSM as well as a set of reaction-diffusion equations to track the change of geometry, which can be directly correlated to the loss of material. The derived equations were also able to capture the formation of the corrosion film that decreases the rate of degradation. Another comprehensive mathematical model was developed by Sanz-Herrera et al. to investigate the role of multiple chemical components involved in the *in vitro* degradation of Mg implants [69]. One important drawback of this study was its 2D nature. Although the computational model was capable of studying the effect of multiple components, due to the high number of derived equations, it would be difficult to extend and use the same model for real 3D implants. Additionally, a 2D model cannot capture the full phe-

nomenon of corrosion, and as a result, the validation of the model will be more qualitative. It was shown in the study conducted by Gao et al. [59], where they compared the results of a multi-dimension model of the degradation of cardiovascular stents with those of a single-dimension model, that the number of considered dimensions had an important effect on the model predictions. In the end, it is worth mentioning that no dedicated experiments were performed in the aforementioned studies to validate the constructed mathematical and computational models.

The current study focuses on developing a physicochemical model of the biodegradation process of commercially-pure (CP) Mg biomaterials by continuing the work of Bajger et al. [68]. In this model, a set of partial differential equations (PDE) was derived according to the underlying chemistry of biodegradation, described as reaction-diffusion processes taking place at the interface of the biomaterial and its surrounding environment. The formation of a protective layer, effects of the ions in the solution, and the change in the pH due to the corrosion phenomenon were taken into account in the mathematical model. The corresponding computational model was implemented in a fully parallelized manner. Model calibration and validation were executed using data obtained from the immersion tests performed in saline (NaCl) and simulated body fluid (SBF) solutions.

3.2 Background theory

3.2.1 Biodegradation as a reaction-diffusion system

The biodegradation process can be considered as a reaction-diffusion system [77], in which the ions are released due to the chemical reactions on the surface, and the released ions diffuse through the surrounding solution and materials. These ions can interact with other ions and form new compounds [35]. As the reaction-diffusion systems have been studied in science and engineering for a couple of decades, the analogy with a reaction-diffusion system makes it convenient to construct a mathematical model of the biodegradation process based on the well-established transport phenomena equations [78]. From the mathematical perspective, a reaction-diffusion system is expressed by a set of parabolic PDEs that describe the conservation of contributing chemical species in the studied system.

3.2.2 Moving boundary - Stefan problems

Moving boundary problems, also called Stefan problems, are the general class of mathematical problems in which the boundary of the domain should also be calculated in addition to the solution of the other equations [79]. Coupling the reaction-diffusion system of biodegradation with a moving boundary problem constructs a mathematical model in which the change of the domain geometry due to the material loss can be correlated to the underlying reaction and diffusion processes of corrosion. As the geometry can be determined accurately, this approach provides a way to measure the mass loss directly by computing the change in the volume of the material. In such a system, the moving boundary is the material-solution interface (corrosion front).

For a 1D corrosion diffusion system, the position of the diffusion interface can be determined by [79]:

$$s(t) = s_0 + 2\alpha\sqrt{t}, \quad (3.1)$$

in which the $s(t)$ represents the position at any given time, and s_0 is the initial interface position. α coefficient can be calculated using:

$$\alpha = \frac{[\text{Mg}]_0 - [\text{Mg}]_{\text{sat}}}{[\text{Mg}]_{\text{sol}} - [\text{Mg}]_{\text{sat}}} \sqrt{\frac{D}{\pi}} \frac{\exp\left(\frac{-\alpha^2}{D}\right)}{\text{erfc}\left(\frac{-\alpha}{\sqrt{D}}\right)} \quad (3.2)$$

where $[\text{Mg}]_{\text{sol}}$ is the concentration in the solid bulk (i.e. materials density) and $[\text{Mg}]_{\text{sat}}$ is the concentration at which the material is released to the medium. $[\text{Mg}]_0$ represents the initial concentration of the metallic ions in the medium, which is usually zero for most corrosion cases.

Eqs. 3.1 and 3.2 can be used to simply track the movement of the corrosion front, which is the employed method in studies like the Gorgan et al. work [66], but apparently, the real-world corrosion problems are 3D and much more complex than the described system.

As will be described later, Eq. 3.1 is used strictly for the first time step of the simulations in low diffusion regimes for calculating the initial velocity of the interface. Generally speaking, a more sophisticated approach, such as the level set method, is required for tracking the interface of complex 3D geometries.

3.2.3 Level-set method

In the current study, the corrosion front is tracked using an implicit function such that the zero iso-contour of the function represents the metal-solution

interface. As a common practice, this implicit function is expressed as a signed distance function that defines the distance of each point of space (the domain of interest) to the interface. Such a definition implies that the zero iso-contour of the function belongs to the interface. The level set method provides an equation to declare such an implicit function, $\phi = \phi(\mathbf{x}, t)$, $\mathbf{x} \in \Omega \subset \mathbb{R}^3$, which can be obtained by solving [80]:

$$\frac{\partial \phi}{\partial t} + \vec{V}^E \cdot \nabla \phi + V^N |\nabla \phi| = b\kappa |\nabla \phi| \quad (3.3)$$

in which \vec{V}^E is the external velocity field, and V^N is the value of the normal interface velocity. The last term is related to the curvature-dependent interface movement and is omitted. As the effect of perfusion is neglected in the current study, the term containing the external velocity is also eliminated, resulting in the following simplified form of the level set equation:

$$\frac{\partial \phi}{\partial t} + V^N |\nabla \phi| = 0. \quad (3.4)$$

By having the normal velocity of the interface (V^N) at each point and solving Eq. 3.4, the interface can be captured at the zero iso-contour of the ϕ function.

3.3 Materials and methods

3.3.1 Underlying chemistry

The chemistry of biodegradation of Mg depends considerably on the surrounding solution and the presence of certain ions [35]. In NaCl solutions, the anodic and cathodic reactions as well as the formation and elimination of side corrosion products can be considered as follows [2]:

Reaction 3.6 is not fully correct from the chemical point of view. In fact, Mg surface is always covered by MgO layer, and $\text{Mg}(\text{OH})_2$ forms on top of that either at atmospheric conditions or during the immersion. The integrity of this MgO layer is undermined by Cl^- ions, leading to an increase in degradation rate:

Although Cl^- formally does not participate in reaction 3.7, it reflects the dependence of Mg corrosion rate on Cl^- concentration. This effect on the rate of degradation has been widely expressed as the effect of Cl^- on the $\text{Mg}(\text{OH})_2$ in the literature [2, 5]. In the developed model, this effect is used interchangeably by omitting the MgO component, so the protective film formed on the corrosion interface is assumed to contain $\text{Mg}(\text{OH})_2$ only. Moreover, it has been shown recently that oxygen reduction reaction also takes place during corrosion of Mg [33, 81, 82]. However, this is a secondary reaction (complementing water reduction) contributing to 1-20% of the total cathodic current depending on the conditions. Hence, it is not taken into consideration in this model. Additionally, the involved chemical reactions are more complicated in SBF solutions due to the presence of further inorganic ions and the formation of a layered precipitate structure [35], but the effect of these ions is currently encapsulated in the reaction rates and the diffusion coefficients of the developed mathematical model. The summary of the considered chemistry to develop the mathematical model is depicted in Fig. 3.1.

Figure 3.1: The chemistry of biodegradation of Mg considered in the current study: 1) Mg oxidation and water reduction processes accompanied by releasing Mg^{2+} and OH^- ions as well as H_2 gas, 2) formation of a partially protective precipitation layer, 3) dynamic solubility equilibrium and contribution of Cl^- .

3.3.2 Mathematical modeling

To keep track of the concentration changes of various contributing chemical components, we define four state variables for the concentration of Mg^{2+} ions, protective film ($\text{Mg}(\text{OH})_2$), chloride (Cl^-) ions, and the hydroxide (OH^-)

ions:

$$\begin{aligned} C_{\text{Mg}} &= C_{\text{Mg}}(\mathbf{x}, t), & C_{\text{Film}} &= C_{\text{Film}}(\mathbf{x}, t) \\ C_{\text{Cl}} &= C_{\text{Cl}}(\mathbf{x}, t), & C_{\text{OH}} &= C_{\text{OH}}(\mathbf{x}, t) \quad \mathbf{x} \in \Omega \subset \mathbb{R}^3, \end{aligned} \quad (3.8)$$

which are indeed 4 scalar functions of space and time. Ω denotes the whole region of interest, including both the Mg bulk and its surrounding medium. By doing this, the value of pH at each point of Ω can be calculated as:

$$\text{pH} = 14 + \log_{10} C_{\text{OH}}, \quad (3.9)$$

where C_{OH} implies the activity of OH^- . By having the definition of the state variables in Eq. 3.8, the biodegradation of Mg described by Eqs. 3.5 and 3.6 can be represented as a set of reaction-diffusion PDEs:

$$\frac{\partial C_{\text{Mg}}}{\partial t} = \nabla \cdot (D_{\text{Mg}}^e \nabla C_{\text{Mg}}) - k_1 C_{\text{Mg}} \left(1 - \beta \frac{C_{\text{Film}}}{[\text{Film}]_{\text{max}}} \right) + k_2 C_{\text{Film}} C_{\text{Cl}}^2 \quad (3.10)$$

$$\frac{\partial C_{\text{Film}}}{\partial t} = k_1 C_{\text{Mg}} \left(1 - \beta \frac{C_{\text{Film}}}{[\text{Film}]_{\text{max}}} \right) - k_2 C_{\text{Film}} C_{\text{Cl}}^2 \quad (3.11)$$

$$\frac{\partial C_{\text{Cl}}}{\partial t} = \nabla \cdot (D_{\text{Cl}}^e \nabla C_{\text{Cl}}) \quad (3.12)$$

$$\frac{\partial C_{\text{OH}}}{\partial t} = \nabla \cdot (D_{\text{OH}}^e \nabla C_{\text{OH}}) + k_2 C_{\text{Film}} C_{\text{Cl}}^2 \quad (3.13)$$

in which the maximum concentration of the protective film can be calculated according to its porosity (ϵ) [68]:

$$[\text{Film}]_{\text{max}} = \rho_{\text{Mg}(\text{OH})_2} \times (1 - \epsilon). \quad (3.14)$$

D^e is the effective diffusion coefficient for each component. Due to the formation of the protective film, the diffusion coefficient is not constant and varies from the actual diffusion coefficient of the ions to a certain fraction of it. This fraction can be defined as ϵ/τ [83,84], in which ϵ and τ are the porosity and tortuosity of the protective film, respectively. The effective diffusion coefficient can be then calculated by interpolating the two aforementioned values:

$$D_i^e = D_i \left(\left(1 - \beta \frac{C_{\text{Film}}}{[\text{Film}]_{\text{max}}} \right) + \beta \frac{C_{\text{Film}}}{[\text{Film}]_{\text{max}}} \frac{\epsilon}{\tau} \right). \quad (3.15)$$

The β coefficient is called momentum here and controls the effect of the saturation term $(1 - \frac{C_{\text{Film}}}{[\text{Film}]_{\text{max}}})$.

3.3.3 Interface movement formulation

In order to take advantage of the level set method for tracking the corrosion front, the velocity of the interface at each point should be determined. Then, by solving Eq. 3.4, the interface is obtained at the points with a zero value of the ϕ function. The interface velocity in mass transfer problems can be calculated using the Rankine–Hugoniot equation [85], and by considering the transportation of Mg^{2+} ions, it can be written as:

$$\{\mathbf{J}(x, t) - ([\text{Mg}]_{\text{sol}} - [\text{Mg}]_{\text{sat}}) V(x, t)\} \cdot \mathbf{n} = 0 \quad (3.16)$$

where \mathbf{J} is the mass flux at the interface. Rearranging Eq. 3.16 and inserting the value of the normal interface velocity into Eq. 3.4 yields:

$$\frac{\partial \phi}{\partial t} - \frac{D_{\text{Mg}}^e \nabla_n C_{\text{Mg}}}{[\text{Mg}]_{\text{sol}} - [\text{Mg}]_{\text{sat}}} |\nabla \phi| = 0, \quad (3.17)$$

which is the final form of the level set equation to be solved. In the case of simulations with a low diffusion rate, the interface moves slowly in the beginning, which results in a linear degradation, whereas based on the experimental results, the degradation rate is fast at the beginning and slows down eventually [36]. So, to mimic the same behavior in the low diffusion regimes, we took advantage of the theoretical Stefan formulation (Eqs. 3.1 and 3.2) to push the interface in the first time step. According to Eq. 3.1, the velocity of the interface can be calculated as $(2\alpha/\sqrt{t})$, but as we are dealing with a 3D model and not a 1D one, we pick a fraction (denoted by γ) of this ideal value to be used as the driving force of the interface at the beginning of the simulation. So, the normal velocity of the interface can be written in the general form as:

$$V^N(x, t) = \begin{cases} \gamma \frac{2\alpha}{\sqrt{t}} & t = 0 \\ \frac{D_{\text{Mg}}^e \nabla_n C_{\text{Mg}}}{[\text{Mg}]_{\text{sol}} - [\text{Mg}]_{\text{sat}}} & t > 0 \end{cases} \quad (3.18)$$

in which the α value should be calculated from Eq. 3.2. By selecting γ equal to zero, the Stefan formulation can be eliminated, and a value of 1 for γ restores the ideal 1D velocity definition.

3.3.4 Boundary conditions

The implementation of boundary conditions is relatively challenging and complex for the developed model as they should be imposed inside the domain of interest on virtual interfaces defined by mathematical expressions

(i.e. on the moving interface defined by the zero iso-contour of the level set equation). The penalty method was used to overcome this issue and define the desired boundary conditions on the moving corrosion front.

Fig. 3.2 demonstrates a schematic presentation of the boundary conditions and general considerations of each PDE of the biodegradation mathematical model. This figure is divided into 5 different parts, presenting the 5 PDEs of the model. The Mg block is depicted in the center, and the interface separates it from the surrounding medium. There is no specific boundary condition for the level set and film formation equations, but in comparison to the other 3 transport equations, it should be noted that diffusivity is not considered for $\text{Mg}(\text{OH})_2$, which is also reflected in Eq. 3.11. The level set function ϕ is defined in a way that is positive inside and negative outside the solid region. For the Mg^{2+} ions transport equation, a Dirichlet boundary condition is applied on the mathematical interface to make the concentration equal to the saturation concentration of Mg^{2+} ions, a value that was already used in Eq. 3.17. For the Cl^- and OH^- ions transport equations, a no-flux boundary condition is applied to the interface by making the diffusion coefficient equal to zero inside the Mg block, preventing ions to diffuse inside the solid material.

3.3.5 Implementation

To simulate the developed mathematical model, which is comprised of Eqs. 3.10, 3.11, 3.12, 3.13, and 3.17, a combination of finite difference and finite element methods was used, leading to discrete forms of these equations, which were subsequently solved using appropriate linear solvers.

To discretize the temporal terms of the aforementioned parabolic PDEs, a first-order backward Euler finite difference scheme was used, whereas the spatial terms were converted to a weak form using a standard first-order finite element scheme. Then, the open-source PDE solver FreeFEM [86] was used to implement the weak form and obtain a linear system of equations for each PDE. The obtained linear systems were solved in parallel using the HYPRE preconditioner [87] and the GMRES solver [88] via the open-source high-performance computing (HPC) toolkit PETSc [89]. Additionally, to increase the efficiency of the computation and decrease the simulation execution time, the computational mesh was decomposed and distributed among available computing resources using the interface of HPDDM package in FreeFEM [90]. The details of this implementation are presented in Chapter ???. A simple iterative solver based on the Newton method was also developed to solve Eq. 3.2 to obtain the value of α parameter if it was required in the simulations.

The computational mesh was generated using a set of first-order tetrahe-

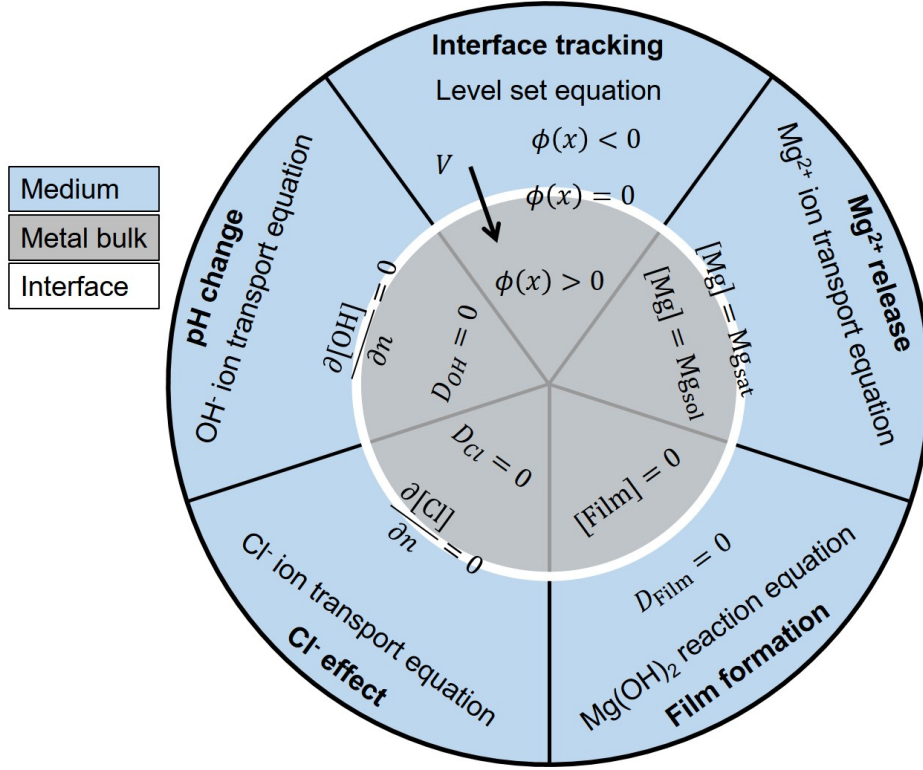

Figure 3.2: A schematic overview of the exposed boundary conditions and constraints required for the simulation of each equation of the developed mathematical model for Mg biodegradation.

dral elements and was adaptively refined on the metal-solution interface to increase the numerical accuracy of the simulation of the level set equation (Eq. 3.17). The Netgen mesh engine [91] in the SALOME platform [92] was used to generate the mesh.

Similar to the technique employed by Bajger et al. [68], the gradient of concentration of Mg^{2+} in Eq. 3.17 was calculated at a distance h in the normal direction from the interface, with h being the smallest element size of the mesh:

$$\nabla_n C = \frac{C(\mathbf{x} + h.n) - C(\mathbf{x} + 2h.n)}{h} \quad \mathbf{x} \in \Omega \subset \mathbb{R}^3. \quad (3.19)$$

Considering the adaptively refined mesh, the h value is very small, so the gradient is computed at the regions close enough to the interface. In addition to this technique, the mass lumping feature of FreeFEM was used to prevent the oscillation of concentration values on the diffusive metal-medium interface.

3.3.6 Experimental setup

The degradation rate of CP Mg was evaluated based on the hydrogen evolution tests performed either in NaCl or SBF solutions with eudiometers. The composition of the electrolytes is shown in the following table (Table 3.1). 0.5 g metallic chips (with a surface area of $47.7 \pm 5.0 \text{ cm}^2/\text{g}$ and chip thickness ca. 200 microns) of CP Mg were put in 500 ml electrolyte for 22-24 hours for monitoring the amount of evolved hydrogen. The method of measuring evolved hydrogen was chosen for monitoring the degradation rate because although such a measurement is prone to experimental errors such as relatively high solubility of hydrogen in water and volume change due to temperature and pressure variations, it provides a continuous assessment of the process, resulting in a continuous and smooth curve. Additionally, as small metallic chips were used for the tests, it was not possible to clean these pieces in chromic acid without losing them to measure the mass loss directly. The drawback of choosing the evolved hydrogen as the monitoring method is that it is not the only occurring reaction since oxygen reduction also takes place during the process [33, 81, 82]. As a result, measuring only hydrogen does not capture the totality of the degradation reactions. However, for CP Mg, the contribution of oxygen reduction is low (in contrast to high-purity Mg [33]) and can simply be ignored, meaning that the evolved hydrogen is an accurate equivalent for the mass loss. The bulk pH of electrolytes before and after corrosion was measured by a pH meter (Metrohm-691, Switzerland). Local pH was measured by positioning pH microprobes (Unisense, Denmark, pH-sensitive tip size 10x50 micron) 50 micron above the surface of Mg and monitoring the pH values either in one spot or by horizontal or vertical line-scans or mapping by following a horizontal grid. The electrolytes were not pH buffered additionally since SBF contains carbonates and phosphates that stabilize the pH at the approximate value of 8.5 instead of the 10.5 characteristic for pure NaCl solutions where pH is stabilized by precipitation of $\text{Mg}(\text{OH})_2$. Meanwhile, synthetic pH buffers, such as TRIS and HEPES were proven to affect the degradation mechanism rather significantly and should not be used for this purpose [35]. The measurements were performed at room temperature of $22 \pm 2^\circ\text{C}$ maintained by the laboratory climate control system. More detailed information about experimental set up and procedures can be found elsewhere [36, 40].

3.3.7 Parameter estimation

The constructed mathematical model contains some parameters that need to be calibrated prior to final validation of the model: diffusion coefficient of

Table 3.1: Chemical composition of NaCl and SBF electrolytes used to perform hydrogen evolution tests, weight loss, local and bulk pH measurements.

	Concentration/ mM	
	0.85 wt. % NaCl	SBF
Na^+	145.4	142.0
K^+	-	5.0
Mg^{2+}	-	1.5
Ca^{2+}	-	2.5
Cl^-	145.4	147.8
HCO_3^-	-	4.2
$\text{HPO}_4^{2-}/\text{H}_2\text{PO}_4^-$	-	1.0
SO_4^{2-}	-	4.2
Synthetic pH buffer (i.e. Tris/HCl, HEPES)	No	No
Initial pH value	5.6-5.9	7.35-7.45

Mg^{2+} and Cl^- ions (D_{Mg} and D_{Cl} to be inserted into Eq. 3.15 to get effective diffusion coefficients), the reaction rates of Eqs. 3.5 and 3.6 (k_1 and k_2), the momentum parameter, β , for controlling the saturation term behavior (in Eqs. 3.10, 3.11, and 3.15), and the γ parameter for the initial interface velocity (Eq. 3.18). An inverse problem setup was required to estimate the proper value of these parameters.

Performing a parameter estimation requires running the computational models several times. Considering the computationally-intensive model of the current study, a sensitivity analysis was performed prior to the parameter estimation to exclude non-essential parameters and reduce the time required to complete the inverse problem run. This sensitivity analysis was accomplished separately in the low diffusion (similar to the SBF solution) and high diffusion (similar to NaCl solution) regimes.

After determining the essential parameters to include, a Bayesian optimization approach [93] was used to construct the inverse problem and calibrate the parameters. The reason for choosing a Bayesian approach was to minimize the number of optimization iterations, in each of which the simulation should run once. The Bayesian optimization is a more efficient option for such computational intensive cases in comparison to gradient-based or fully-stochastic methods as it takes into account all the preceding iterations in a probability tree [94].

The objective function of the optimization problem was the difference between the predicted and experimentally obtained values of evolved hydrogen.

In the computational model, the evolved hydrogen can be computed directly at any time through the mass loss as each mole of corroded Mg is correlated to one mole of released hydrogen (Eq. 3.5). The mass loss can be obtained using the following volume integral:

$$\text{Mg}_{\text{lost}} = \int_{\Omega_+(t)} [\text{Mg}]_{\text{sol}} dV - \int_{\Omega_+(0)} [\text{Mg}]_{\text{sol}} dV, \quad (3.20)$$

where $\Omega_+(t) = \{\mathbf{x} : \phi(\mathbf{x}, t) \geq 0\}$, and then, the amount of produced hydrogen is calculated using the ideal gas law:

$$H_f = \frac{\text{Mg}_{\text{lost}}}{\text{Mg}_{\text{mol}}} \frac{RT}{P} \quad (3.21)$$

in which R , P , T , Mg_{mol} are the universal gas constant, the pressure, the medium temperature, and the molar mass of Mg, respectively.

3.3.8 Simulation setup

In order to simulate the developed mathematical model, the experimental setup was reconstructed *in silico* with some minor differences. As there is no perfusion in the solution chamber, the mixing effect was neglected, so, as can also be seen in the mathematical model, the advection terms were not considered. Furthermore, the experiments were conducted using small metallic chips, yet, as the biodegradation behavior heavily depends on the exposed surfaces, we represented these chips by a cuboid with the same surface-to-mass ratio. By considering the approximate surface-to-mass of $50\text{cm}^2/\text{g}$ and the total mass of 0.5g , the chips were replaced by a cuboid with the size of $60\text{mm} \times 21\text{mm} \times 0.2\text{mm}$, which approximately has the same ratio, surface area, volume, and mass. Also, the solution chamber with a capacity of 500ml was represented by a cubic container with an edge size of 80mm . Fig. 3.3 depicts the constructed geometry as well as the computational mesh generated to represent it. The mesh is refined on the interface and contains 18,049,471 elements, resulting in 3,077,227 degrees of freedom (DOF) for each PDE.

Simulations were carried out on the VSC (Flemish Supercomputer Center) supercomputer. Taking advantage of HPC techniques to parallelize the simulation is an inevitable aspect of such a computational-intensive model, so based on what described in the implementation section, the mesh was decomposed among 170 computing cores, i.e. 24,137 DOF per core (which includes the ghost nodes to satisfy the boundary condition in each sub-mesh). On the VSC supercomputer, we made use of 5 nodes, 36 cores each, each

Figure 3.3: Computational representation of the experimental set-up, used to perform parameter estimation and numerical validation of the developed model. a) A cuboid of Mg ($60\text{mm} \times 21\text{mm} \times 0.2\text{mm}$) inside a solution, b) a cross-section of the computational mesh, refined on the corrosion front to increase the required level set accuracy.

node holding CPUs with a clock speed of 2.6 GHz, with 960 GB of the total available memory.

The OH^- transport equation (Eq. 3.13) was not solved during the parameter calibration process. Afterwards, two full simulations (for the NaCl and SBF solutions) were conducted to calculate the pH changes based on the change of the concentration of OH^- ions in the medium. This acted as the validation of the numerical model because no calibration was performed on the output of this equation. The pH was calculated using Eq. 3.9, based on the solution of Eq. 3.13 and a reported value of $7.00e \times 10^{-5}\text{cm}^2/\text{s}$ ($25.2\text{mm}^2/\text{hour}$) for the diffusion coefficient of OH^- ions (D_{OH} to be used in Eq. 3.15) in aqueous solutions [95].

According to the experimental setup, the initial concentration of the Mg^{2+} , Cl^- , and OH^- ions were set to 0 (no Mg^{2+} ions at the beginning), 146mM ($5.175 \times 10^{-6}\text{g}/\text{mm}^3$), and $1 \times 10^{-7}\text{g}/\text{mm}^3$, respectively. The porosity (ϵ) and tortuosity (τ) of the protective film were considered to be 0.55 and 1, respectively [76]. The saturation concentration $[\text{Mg}]_{\text{sat}}$ was set to the solubility of magnesium chloride in water, which is $134 \times 10^{-6}\text{g}/\text{mm}^3$ at 25°C [96]. The density of Mg ($[\text{Mg}]_{\text{sol}}$) and $\text{Mg}(\text{OH})_2$ were set to $1735 \times 10^{-6}\text{g}/\text{mm}^3$ and $2344 \times 10^{-6}\text{g}/\text{mm}^3$, respectively [68]. A time step convergence study was performed to determine the implicit time step size. Based on the results, a time step with a size of 0.025 hours was chosen. The overall simulated time is 22 hours in accordance with the experimental design of performed immersion tests.

3.3.9 Case study

To further investigate the predictions of the current model on more complex shapes, the biodegradation of a simple screw was studied in the SBF solution using the parameters obtained for the low diffusion regimes. Similar to the simulation of Mg cuboid, the mesh was refined on the metal-medium interface, and it consisted of 1,440,439 elements with 246,580 DOFs for each PDE. All the simulation parameters and materials properties were identical to the simulation of biodegradation in the SBF solution, and the target was to simulate 42 days (1008 hours) of the process. This was selected as a sufficiently long simulated time to observe the effects of biodegradation on larger time scales. The goal of this case study is to demonstrate the applicability of the developed model for any desired 3D shape with no geometrical limitations. As a result, although it was possible to consider a more complicated geometry for the screw (for example by considering threads around the cylindrical part of the screw or having a realistic geometry for the head), the screw geometry consists of basic 3D primitives, which are adequate for the mentioned purpose.

3.4 Results

3.4.1 Optimization results

Based on the performed sensitivity analysis, two parameter sets were obtained for the high diffusion (in NaCl solution) and low diffusion (in SBF solution) simulations, respectively. These parameters are listed in Table 3.2. According to the results, the reaction rate of Eq. 3.5 (k_1), which demonstrates the rate of oxidation-reduction, has less contribution to the process in comparison to the rate of the weakening of the protective film (k_2). Because of this, the parameter k_1 was not selected for the parameter estimation. Also, the model was sensitive to the effect of parameter k_2 in different ranges of values and not on a specific point, and as a result, three constant values were chosen as the delegates of these ranges in the optimization process. The model was not sensitive to the diffusion rate of Cl^- ions, which was also expected because although Cl^- has an important role in the weakening of the partially protective MgO film, its transport equation (Eq. 3.12) is purely diffusive and does not include any reaction term.

The parameter optimization process was performed on the specified range of selected parameters, while the rest of the parameter values were obtained from the literature [68,95]. Table 3.3 shows the output of this process, which was used to simulate the full model. For two estimation processes, 120 opti-

Table 3.2: The effective parameters as the result of the sensitivity analysis and their corresponding range to be considered in the Bayesian optimization for parameter calibration

	Parameter	Optimization range
Low diffusion (SBF solution)	D_{Mg}	[0.0001, 0.01]
	k_2	$10^{10}, 10^{15}, 10^{20}$
	β	[0.1, 10]
	γ	[0, 1]
High diffusion (NaCl solution)	D_{Mg}	[0.003, 0.1]
	k_2	$10^{10}, 10^{15}, 10^{20}$
	β	[0.1, 10]

Table 3.3: Values used to evaluate the model performance, obtained from the output of the optimization process and the literature.

Parameter	D_{Mg}	D_{Cl}	D_{OH}	k_1	k_2	β	γ
Unit	$\frac{\text{mm}^2}{\text{hour}}$	$\frac{\text{mm}^2}{\text{hour}}$	$\frac{\text{mm}^2}{\text{hour}}$	$\frac{1}{\text{hour}}$	$\frac{\text{mm}^6}{\text{g}^2\text{hour}}$	-	-
SBF solution	0.000338	0.05	25.2	7	10^{15}	0.125	0.65
NaCl solution	0.06273	0.05	25.2	7	10^{20}	0.2	0

mization iterations were taken cumulatively, which took 276 hours of simulation execution time using 170 computing nodes for each simulation.

3.4.2 Degradation prediction

Fig. 3.4 shows the model output for the predicted produced hydrogen, protective film formation, and the pH changes. The graph of the evolved hydrogen is used as input during the parameter optimization process, but the pH results are produced by the simulations using the optimized parameters to demonstrate the validation of the developed mathematical and computational models. The predicted pH result (Fig. 3.4-d) shows a difference of 5.35% for the simulation in NaCl and 1.03% for SBF simulation. Each simulation took about 3 hours to complete.

In Fig. 3.4, a post-processed view of the final shape of the Mg cuboid in the NaCl solution is presented, in which the degraded geometry is plotted on the Mg^{2+} ions (Fig. 3.4-b) and protective film concentration (Fig. 3.4-c) contours. A transparent contour of the pH values in the solution is depicted for both the NaCl (Fig. 3.4-e) and SBF (Fig. 3.4-f) solutions. The range of colors is kept equal for both contours to make it easy to compare the change

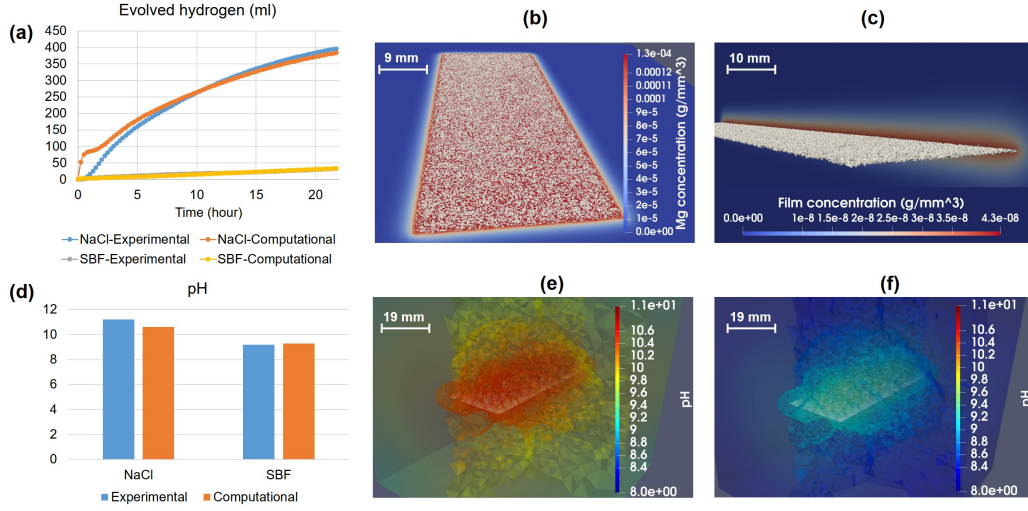

Figure 3.4: Comparing the quantitative output of the model for the rate of degradation and the pH changes in NaCl and SBF solutions with experimentally measured values as well as the simulation results for ion release, mass loss, protective film formation, and pH changes after 22 hours of simulated time: a) calibrated output of the formed hydrogen gas during the degradation (the SBF curves are overlapped), b) the simulation results of Mg^{2+} ions release, c) the simulation results of protective film concentration at the end of the simulation (the color contour shows the concentration of species, and the gray surface is the zero iso-contour of the level set function, which indicates the surface of the Mg block), d) de novo prediction of the global pH changes in the medium, showing a good agreement between the model output and the experimental results, e) pH changes in different regions of the medium in NaCl solution, f) pH changes in SBF solution.

of pH in both solutions.

The concentration values of the state variables of the derived transport PDEs (Mg^{2+} , Cl^- , OH^- , and $\text{Mg}(\text{OH})_2$) are plotted along a diagonal line in the solution container in Fig. 3.5, showing how they change in the zones close to the corrosion surface and far from it.

3.4.3 Example application

The simulation of 42 days (19,200 time steps) of the degradation of the simple screw took 9 hours to run using 170 computing cores. Fig. 3.6 depicts the post-processed interface and Mg^{2+} ions release (similar to Fig. 3.4-b) as well as the mass loss during the degradation of the screw in the SBF solution. It

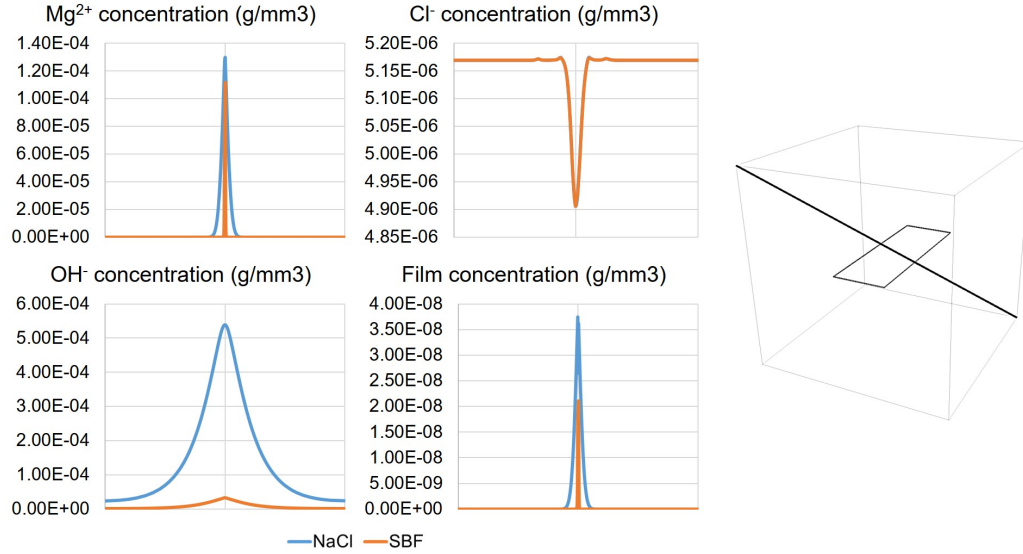

Figure 3.5: The change of concentration for the involved chemical components, Mg^{2+} , Cl^- , OH^- ions, and the protective precipitation structure (which can be correlated to the thickness of the layer) plotted over a diagonal line as shown in the right.

is worth mentioning that the roughness observed on the surface of the screw geometry is related to the node-based visualization of the level-set function evolution and is not caused by either non-uniform corrosion or numerical error in the simulations.

3.5 Discussion

In this study, a physicochemical model of the biodegradation process of commercially-pure Mg was developed by constructing a mathematical model formulating the mass transfer phenomena as well as tracking the location of the surface of the implant during degradation. For the mass transfer model, the equations were derived from the chemistry of biodegradation of the Mg in saline (NaCl) and buffered (SBF) solutions, which includes the oxidation of the metallic part, reduction of water, changes in pH, and formation of a protective film on the surface of the scaffold which contributes to a slower rate of degradation. Beside these aspects, it was also crucial to consider the effect of different ions in the medium on the rate of degradation. Additionally, investigating the structural changes of the scaffolds and implants in practical applications, like resorption of temporary fixation devices, re-

Figure 3.6: A cross-section of the computational mesh and simulation results of the degradation process of the use-case screw in SBF solution as well as the mass loss graph over time. The contours display the concentration of Mg^{2+} ions on a cross-section view of the medium beside the moving surface of the screw at 1) 1st day (initial state), 2) 6th day, 3) 12th day, and 4) 18th day.

quires tracking the movement of the corrosion surface. This was done by constructing an equation based on the level set principle, which captured the movement of the medium-metal interface by defining an implicit surface. The derived equations were coupled and solved using a combination of finite difference and finite element methods. The degradation data to validate the models was collected from immersion tests of small Mg chips, reconstructed as a single cuboid in the computational study with a similar surface over volume properties. The model parameters were calibrated using a Bayesian optimization algorithm, and the obtained parameters were used to simulate the pH changes in NaCl and SBF solutions.

The developed model falls in the categories of physical models of the corrosion process, which provide more insights of the process in comparison to the phenomenological models. The reason is that the phenomenological models focus on the elimination of elements to capture the loss of materials, which makes it impossible to model the formation of new chemical compounds or interaction of species [97]. The physical models, like the one developed in this study, are capable of capturing the underlying chemical interactions. By doing this, processes like the effect of coating, the formation of a protective layer, and pH changes can be modeled. Adding an appropriate interface tracking method enables the physical models to act like the phenomenological models in capturing the corrosion interface movement. In the current study, this has been accomplished using a level set function. Technically speaking, this approach has certain benefits over the ALE method, which is

the method used by several similar studies, including Grogan et al. [66]. In comparison to the ALE method, the level set function tracks the interface instead of a Lagrangian mesh, and elements can freely be marked as solid or liquid. Additionally, employing the ALE method for degradation simulation requires remeshing the geometry as the interface moves, which is not efficient for 3D models and is limited to the available features of the employed numerical solver.

One of the challenging aspects of validating physical models is getting the correct value for the parameters of said models, requiring dedicated experimental input. To overcome this challenge, an efficient inverse problem was constructed based on the Bayesian optimization approach to estimate the unknown parameters. To save time and resources, the parameter estimation process was performed on the most effective parameters, which were selected based on a sensitivity analysis. This selection process implied the importance of parameters in high and low diffusion rates. This included the diffusion coefficients (except the diffusion rate of the hydroxide ion), which were subsequently used in Eq. 3.15 to get the effective coefficient employed in the derived PDEs. The objective function of the optimization process was the difference in the mass loss predicted by the computational model and the experiments, but instead of direct mass loss measurement, we measured the volume of formed hydrogen gas in Mg corrosion, which then was converted to mass loss by considering the stoichiometry of the reactions.

The degradation rate is fast at the beginning, but then it slows down due to the formation of a partially protective film and also because of the saturation concentration. This phenomenon is well captured by the model at high diffusion rates, but in low diffusion rates (in SBF solution), this effect can be reproduced by pushing the corrosion front according to the Stefan formulation of the moving interface problems. This was controlled by the parameter γ (Eq. 3.18). The sensitivity test demonstrated that this parameter doesn't have a significant effect in the high diffusion rates, but for the low diffusion regimes, it was considered in the parameter estimation process. It should be noted that the inclusion of the γ parameter is crucial for short-term simulations only, helping the model mimic the chemical behavior correctly. In other words, the long-term degradation behavior can be successfully simulated without considering the parameter γ . For example, the sensitivity test (Table 3.2) has marked γ as an effective parameter because it plays an important role in the first 22 hours of degradation model behavior. But, for the case study, the result (the graph in Fig. 3.6) would be almost the same with γ set to zero since 40,320 time steps (1008 hours) passed after applying the parameter in the first time step.

For the high diffusion regime simulation, the results show a difference

between the experimental and computational data in the early stages of the degradation process (Fig. 3.4-a). The reason for this behavior lies within Eqs. 3.17 and 3.19, in which the interface velocity was correlated to the gradient of released ions. In high diffusion rates, the material release occurs very fast, so the calculated gradient (Eq. 3.19) vanishes for a short period until the diffusion becomes more uniform. As a result, the interface does not move, and according to Eq. 3.20, no mass loss gets calculated. This effect was automatically ignored in the parameter estimation process since the objective function considers the overall degradation behavior.

The degradation of the CP Mg was assumed to be mostly diffusion-based. As a result, the value of D_{Mg} plays an important role in the behavior of the model. Although it was possible to get the diffusion coefficient of Mg^{2+} from the previously conducted experiments in the literature (similar to what was done for D_{OH}), we decided to not do so because of two reasons: 1) the values reported in the literature are mostly valid for saline solutions only, and 2) the reported values were not in a good agreement with one another [66, 76]. Thus, the diffusion coefficient was obtained using the parameter estimation process for both the NaCl and SBF solutions. The obtained value of D_{Mg} ($0.06273\text{mm}^2/\text{hour}$) was in line with the values that Grogan et al. have already suggested ($0.010575 - 0.50575\text{mm}^2/\text{hour}$) [66], showing that the constructed inverse problem was successful in reproducing previous results of similar studies. The obtained value of D_{Mg} in the Bajger et al. work [68] is $0.00066\text{mm}^2/\text{hour}$, which is mostly related to the simplicity of the employed parameter estimation method as well as having a 2D model instead of a 3D one.

In the *in vitro* biodegradation of Mg-based biomaterials, the local pH of the surrounding solution increases less than that in NaCl solution. This is because the $\text{Mg}(\text{OH})_2$ formed in NaCl stabilizes pH at 10.4 [98], while Mg-Ca-P-C containing products stabilize the pH at 7.8-8.5 since OH^- is consumed for the formation of this product [36, 39]. This phenomenon was captured in Eqs. 3.13 and 3.9 to calculate pH based on the concentration of OH^- ions, showing the local pH changes at any location (Fig. 3.4-e,f). In the current study, the global pH is considered as the validation criterion, which means that the average value of the solution pH is calculated using a volume integral and is compared with the ones obtained from the experiments. Fig. 3.4-d shows that such a prediction has a good agreement with the experimental data.

One of the biggest simplifications of the current study was made by ignoring the contribution of pH changes to the biodegradation mechanism of Mg. Although doing that is relatively simple and straightforward in the approach taken by this study, it results in non-linear terms in the derived PDEs. This

non-linearity inserts another level of complexity to the computational model as the order of the state variables are in the range of 10^{-6} to 10^{-10} , which makes it difficult to yield convergence in the iterative non-linear solvers. By developing a robust non-linear solver, this effect can be added simply by including more relevant terms as the effect of Eq. 3.13 into Eq. 3.10.

Additionally, buffered solutions and the physiological fluids inside the human and animal bodies contain more ions interacting with more complex chemistry [35]. In this study, this effect was encapsulated in a limited number of parameters (such as k_1 and k_2 in Eqs. 3.10, 3.11, and 3.13), but while the results show its success to reproduce experimental observations, it still needs additional elaboration to be able to capture more chemical interactions. For example, SBF solutions contain phosphates, carbonates, and calcium that form hydroxyapatite-like compounds on the surface of Mg, acting as rather strongly blocking corrosion products. In the current state of the developed model, such an effect on the corrosion rate was captured by a low effective diffusion coefficient (Eq. 3.15) for the Mg transport. In future model developments, the effect of presented inorganic ions such as HCO_3^- , $\text{HPO}_4^{2-}/\text{H}_2\text{PO}_4^-$, and Ca^{2+} can be added similar to the way the effect of Cl^- was considered. Additionally, formulating the effect of HPO_4^{2-} that exists in the physiological environments will make the model capable of making more accurate predictions for *in vivo* studies.

A common approach in mechanistic studies is to start with a pure material and gradually increasing complexity by adding impurities and alloying elements. This approach was followed in the current study by beginning with a model for pure Mg that captures the major reactions. The developed model can be further extended to Mg alloys by considering the effect of alloying elements on the reaction rates as well as adding more terms to the transport equations to capture the electrochemical potential changes, converting the PDEs into the Nernst–Planck equation [99]. By doing so, more complex forms of the corrosion process, such as galvanic corrosion, can be predicted by the model. This will increase the applicability of the model for biomedical cases since pure Mg is not commonly used for medical-graded applications. As an additional future development, the corrosion layer can be considered to be heterogeneous, making it possible to simulate the cathodic reactions by randomly distributing more active spots on the surface. Alternatively, a similar effect can be achieved by adapting the degradation rates using polarization curves and introducing an active spot for inhomogeneous anodic dissolution [100]. Applying this will enable the model to take into account additional corrosion products formed due to additional alloying elements such as Zn, Ca, Ag, rare-earth elements, and detrimental cathodic impurities such as Fe.

Although the pH simulations are not enough experimental input to call the model fully validated, the obtained validation results show that the derived mathematical model and the corresponding parallelized computational model give a correct *in silico* representation of the studied process. The performed predictive simulations, including the case study, demonstrate the potential of the developed computational model and software to study the biodegradation behavior of implants. This can be further combined with other computational models to provide a multidisciplinary environment to investigate the mechanical integrity of implants or induced neotissue growth for different applications in orthopedics and tissue engineering.

3.6 Conclusions

The use of biodegradable metals for designing medical devices and implants has the challenge of controlling the release and rate of degradation, which is usually investigated by conducting *in vitro* and *in vivo* tests requiring conducting multiple experiments for different scenarios and situations. In this study, we have developed a mathematical model to predict the biodegradation behavior of commercially pure Mg-based biomaterials, which makes it possible to study the corrosion of implants and scaffolds in a simulated environment. Despite the assumed simplifications, the model can serve as an important tool to find the biodegradable metals properties and predict the biodegradation behavior of Mg-based implants that improves current design workflows.
